

Cyclic Boosting

A Pure-Python, Explainable, and Efficient ML Method

Felix Wick, April 2023

This is old stuff.

But it just works.

Cyclic Boosting ML Methods

family of off-the-shelf, general-purpose supervised machine learning methods for both regression and classification tasks (focus on structured data)

closest relatives: Generalized Additive Models (not a deep learning approach)

main difference: estimation of factors for each bin of the different features (instead of estimation of parameters like coefficients in linear regression or weights in neural networks)

→ individual explainability

scientific papers describing the methods: Cyclic Boosting, Demand Forecasting with Cyclic Boosting

Cyclic Boosting Library

scikit-learn-like usage of library

open source: github

Python package: pypi

documentation: readthedocs

Cyclic Boosting | Different Modes/Scenarios

(conditional mean)

 $Y \in [0, \infty)$

Poisson /
Negative Binomial
distribution
(link function In)

example

demand forecasts (mean)

(conditional mean)

 $Y \in (-\infty, \infty)$

Gaussian
distribution
(link function identity)

example

profit predictions

(probability)

 $Y \in [0, 1]$

Bernoulli distribution (link function *logit*)

example

churn probability

(dispersion parameter)

Y ∈ [0, 1]

Negative Binomial distribution (link function *logit*)

example

demand forecasts as full probability distributions

(elasticity parameter)

Y ∈ [0, ∞)

exponential distribution (link function ln)

example

individual pricedemand elasticities

(conditional mean)

 $Y \in (-\infty, \infty)$

Gaussian distribution (link function identity)

example

individual causal effects, e.g., customer targeting

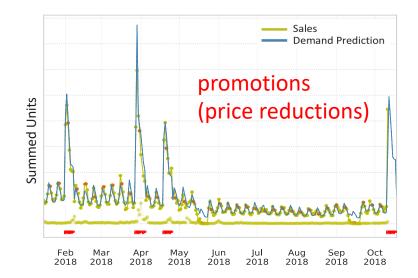

Example Use Case: Demand Forecasting

many individual time series to consider

typical retail grocery chain:

- products (items): ~20k
- locations (stores): ~500
- daily/hourly aggregated sales

advantages of machine learning over traditional univariate time series forecasting

combined learning on all time series of product-location combinations (rather than separately optimizing individual time series)

→ reduces variance by exploiting commonalities

natural consideration of many exogenous variables (prices, promotions, holidays, weather, ...)

→ reduces bias

to be noted:

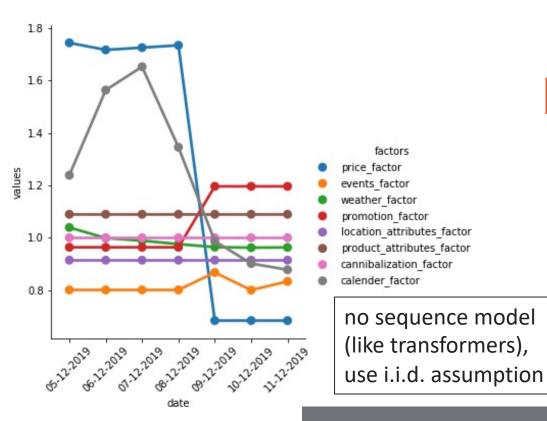

- categorical features important (products and locations → high cardinality)
- mainly multiplicative effects
- demand (approximately) following Poisson (or rather negative binomial) distribution

Cyclic Boosting - Prediction View | Individual Explainability

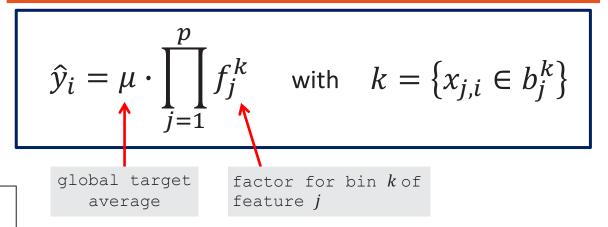

Cyclic Boosting in multiplicative regression mode

individual item-store-day predictions

Cyclic Boosting allows for detailed explanation of each individual prediction by means of contributions (in form of factors) of each feature in the model.

prediction: look up learned factors of relevant bin for each feature

multiplicative model

variation proportional to level

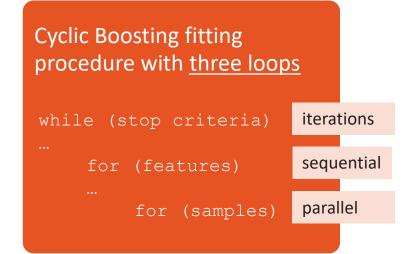

do not confuse explainability with causality though

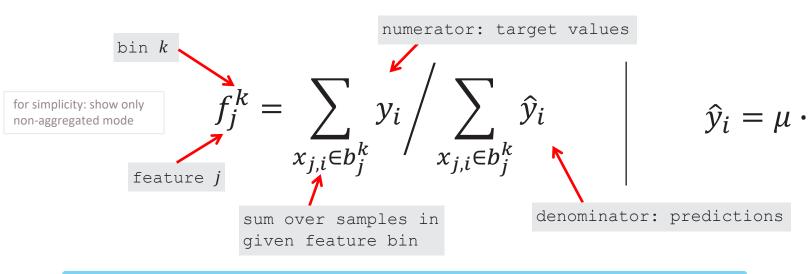

→ need for causal assumptions (e.g., specific smoothing)

Cyclic Boosting Training Coordinate Descent: Boosting-like Update of Factors

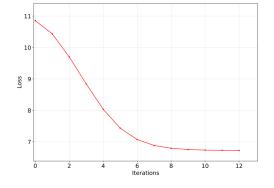

- calculate global average μ , initialize all factors to 1
- cyclically iterate through features and calculate factors for each feature bin (corresponding to minimization of quadratic loss)

other modes work accordingly

stop according to MAD or MSE criteria at end of iterations (full feature cycles) or when reaching given maximal number of iterations

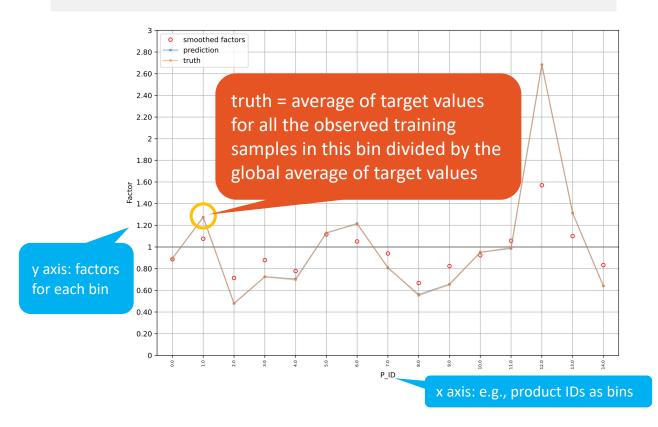

product of factors for all p features in corresponding bins of sample i

Binning

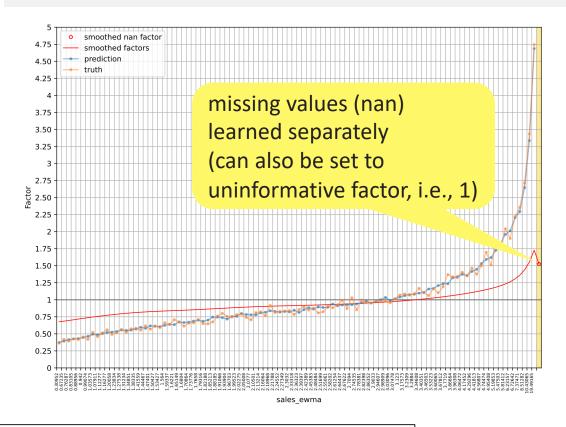

categorical features retain original categories (learning of specific factor for each of the bins)

→ supporting categorical features with high cardinality

continuous features discretized to:

- either having same bin width (equidistant binning)
- or containing approximately same number of observations (equistatistics binning) with different bin widths

local optimization in each bin: allows learning of rare effects with low bias

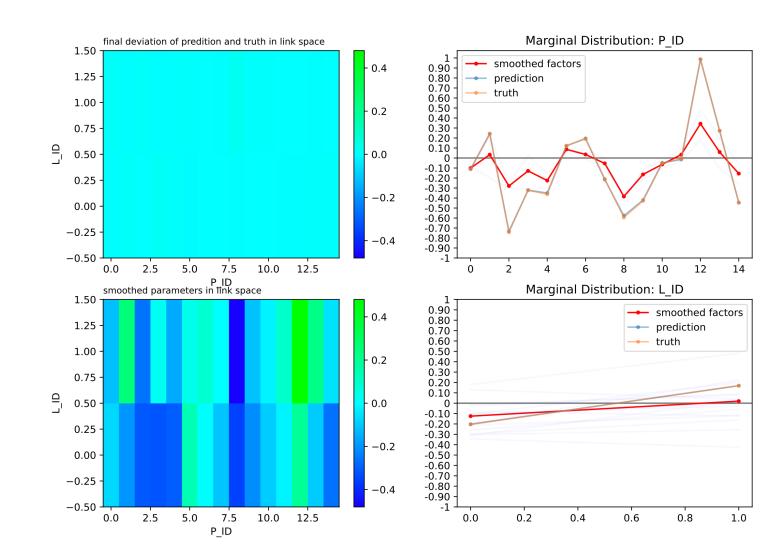

Interaction Terms

e.g., different holiday effects for different products

require even more local optimization (rare effects)

→ include binned interaction terms (e.g., 2D or 3D)

can (partly) enable hierarchical model structure (in combination with coordinate descent): interaction terms with product groups, products, locations

Smoothing

to avoid overfitting:
regularization (smoothing) across bins

→ drastic reduction of variance by
ignoring fluctuations

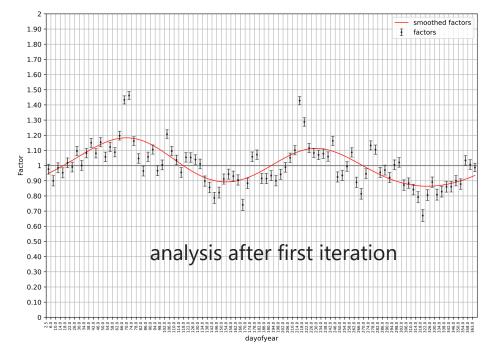

separate smoothings in each iteration

in general: orthogonal polynomials

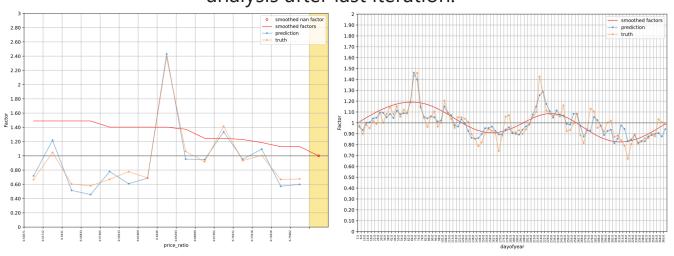

another way to include prior knowledge via

- monotonic requirements
- sinusoidal functions
- (piecewise) linear

use fitted functions (smoothed factors) instead of original factors

analysis after last iteration:

Analysis Plots

support EDA and modeling

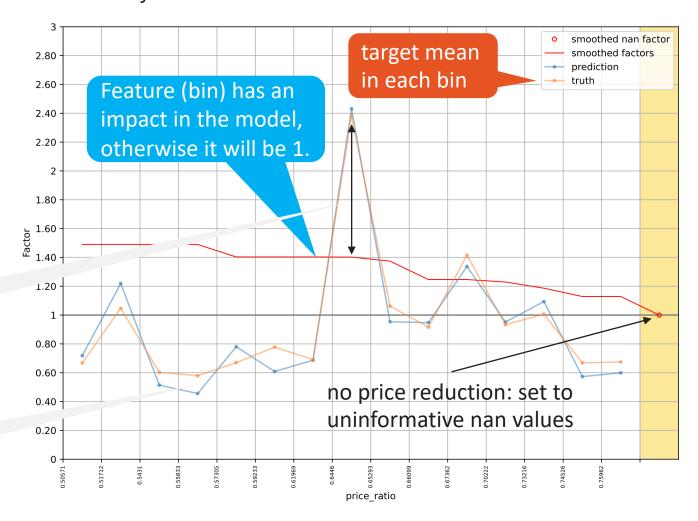

model transparency → ease of development

automatically generated

Deviations between smoothed factors and predictions come from correlations with other features.

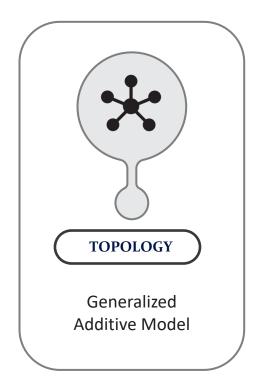

Deviations of predictions from truths show potential model weaknesses (biases) in different bins.

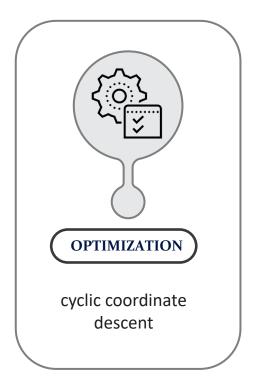

analysis after last iteration:

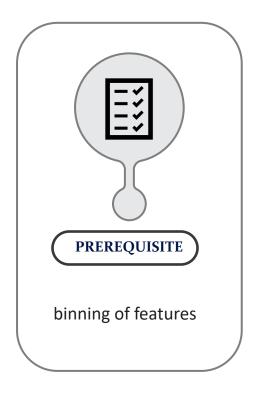

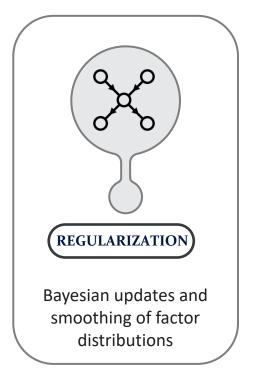

Cyclic Boosting | Characteristics

similarities to:

backfitting, forwardstagewise modeling (aka boosting) LightGBM

Off-The-Shelf Method for Structured Data

- "simple" algorithm, but robust and fast
- few hyperparameters to be tuned
- not much data pre-processing needed
- easily configurable for different data types
- supporting missing values in input data
- assisting model development with individual analysis plots for features
- allowing building of complex models by means of interaction terms
- (multiplicative or additive) regression (location parameter)
- classification

Other Modes: Width Prediction (Scale)

important busines application: automated replenishment

full, individual PDF predictions (e.g., probability distributions for each product-location-day combination)

by means of separate ML models for mean and variance (actually, indirect prediction of variance via dispersion parameter), assuming negative binomial distribution of target (e.g., demand) in maximum likelihood estimation

1. Forecast Probabilities

We understand internal & external factors. By forecasting the probability density, we know the risks of e.g. lost sales vs. waste.

2. Optimize Decisions

Strategy by cost/benefit Vs. ... Reduce Reduce Shrink

Constraints

3. Automate Orders

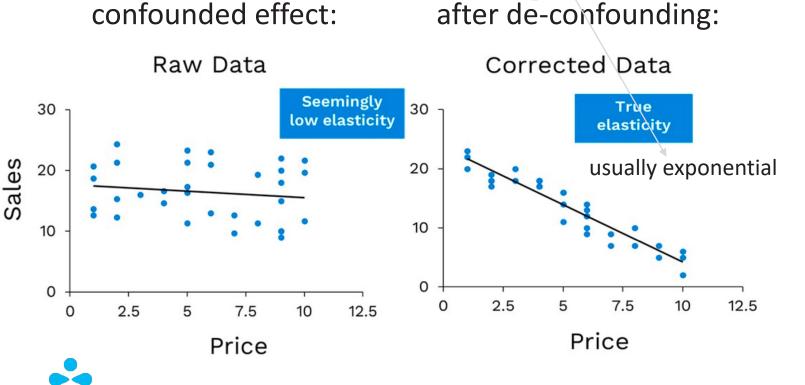

Knowing these risks we calculate the order, which minimizes these risks and balances them according to strategy set by the retailer.

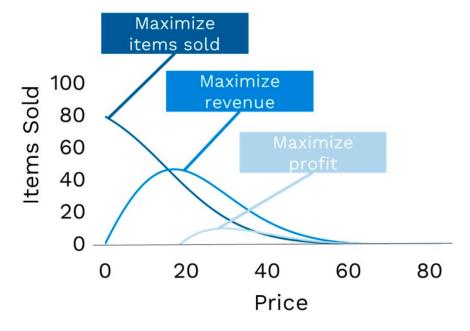

Other Modes: Elasticity Prediction (Shape), Background Subtraction

other business application: demand shaping by causal inference (mainly beyond ML/CB), examples:

- dynamic pricing: influence demand of different products by price setting
- customer targeting: influence individual customer demand by couponing (subtract unaffected customers)

use for pricing policies:

Now Try It Yourself ...

hackathon at Blue Yonder booth

task: retail demand forecasting

You can also try to beat Cyclic Boosting with other methods like Gradient Boosting or a transformer.
